From DEoptim to RcppDE:  
A case study in porting from C to C++  
using Rcpp and RcppArmadillo

Dirk Eddelbuettel  
Debian Project

Abstract

DEoptim (Mullen et al. 2009; Ardia et al. 2010a,b) provides differential evolution optimisation for R. It is based on an implementation by Storn (Price et al. 2006) and was originally implemented as an interpreted R script. It was then rewritten in ANSI C which resulted in a much improved performance.

The present paper introduces another implementation. This version is written in C++ based on the Rcpp package (Eddelbuettel and François 2010) which provides tools for a more direct integration of R objects at the C++ level—and vice versa. It also uses the RcppArmadillo package (François et al. 2010) which provides an interface from R to the Armadillo linear algebra package written in C++ by Sanderson (Sanderson 2010). We find that by rewriting the differential evolution optimisation algorithm in C++, we achieve three usually exclusive goals: a) shorter code, b) easier maintainability as well as improved ability to enhance and extend, and c) consistent performance gains.

Keywords: Rcpp, RcppArmadillo, DEoptim, differential evolution, genetic algorithm.

The DEoptim package was instrumental in creating this paper, and I am grateful to Ardia et al. (2010b). Christian Gunning kindly provided comments and additional references which improved the paper. All remaining errors are mine.

This version corresponds to RcppDE version 0.1.1 and was typeset on April 08, 2012.

1. Introduction

DEoptim (Mullen et al. 2009; Ardia et al. 2010a,b) provides differential evolution optimisation for the R language and statistical environment. Differential evolution (Storn and Price 1997) is one of several evolutionary computing approaches to the global optimisation of arbitrary objective functions; genetic algorithms and simulated annealing are two others. Differential evolution is reasonably close to genetic algorithms but differs in one key aspect: parameter values are encoded as floating point values (rather than sequences of binary digits), which makes it particular suitable for real-valued optimisation problems. The relative performance of differential evolution compared to other global optimisation algorithms, as well as optimal parametrization, is reviewed in Storn and Price (1997) and Vesterstrom and Thomsen (2004).

DEoptim is based on an implementation by Storn (Price et al. 2006). It was originally implemented as an (interpreted) R script before being rewritten in (compiled) C which resulted
in a much improved performance. **DEoptim** has been used to optimise problems from a wide range of problem domains ranging from crystallography (Mullen et al. 2010) to agricultural economics (Börner et al. 2007) and computational finance (Boudt et al. 2008). It is also being used by two other CRAN packages for R: **micEconCES** (Henningsen and Henningsen 2010) and **selectMeta** (Rufibach 2010).

The present paper introduces the R package **RcppDE**. It provides another iteration as far as implementations of differential evolution go. This new version is based very closely on **DEoptim** but written in C++. The implementation employs the **Rcpp** package (Eddelbuettel and François 2010) which provides tools for a more direct integration of R objects at the C++ level—and vice versa. It also uses the **RcppArmadillo** package (François et al. 2010) which provides an interface from R to the **Armadillo** linear algebra package written in C++ by Sanderson (Sanderson 2010).

The code structure descends directly from the current **DEoptim** by Ardia et al. (2010b). The conversion to C++ was undertaken to see whether one or more of the goals shorter, easier and faster could be achieved by switching the implementation language. These goals were loosely defined as follows:

- **shorter** replacing code that is by necessity somewhat verbose when written in C with more compact code written in C++: an example would be copying of a matrix which is implemented as a dual loop copying each element—whereas C++ allows us to use a single (overloaded) + operator and hence a single statement;

- **easier** this may appear as a corollary to the previous point but really covers other aspects such as the automatic type conversion offered by **Rcpp** as well as the automatic memory management: by replacing allocation and freeing of heap-based dynamic memory, a consistent source of programmer error would be eliminated—plus we are not trying ‘short and incomprehensible’ in the APL-sense but aim for possible improvements on both the length and the ease of comprehension without trading one off against the other;

- **faster** this may be a bit more of a conjecture as ultimately, C++ and C can be expected to be roughly equivalent given matching compiler versions etc; however gains maybe be expected from replacing a copying operation of a block of adjacent memory cells with a single **memcpy**() call done behind the scenes; **RcppArmadillo** also offers further possible gains from template metaprogramming which can result in the elimination of temporary object in complex expression where, loosely speaking, compile-time effort is substituted to gain later run-time performance.

This paper is organised as follows. The next sections describes the structure of **DEoptim** which **RcppDE** shadows closely. The following two section compare differences at the R and C++ level, respectively. Next, changes in auxiliary files are discussed before we review changes in performance. A summary concludes. The appendix contains a list of figures contrasting the two implementations.

### 2. **DEoptim** structure

**DEoptim** is a straightforward and well-implemented package. Its core functionality is provided by three R files, as well as three C files.
In the transition **DEoptim** from to **RcppDE** many more changes were made to the C files: besides the obvious porting from C to C++, several internal code changes were made. We discuss these changes below. An important point to note is that the overall architecture and API remain as unchanged as possible. On the other hand, very few changes were required at the R level. The user-facing side of **DEoptim** persists virtually unchanged (with one or two changes discussed below).

Because of the dominant number of changes at the level of the compiled languages, we discuss the structure, and later on changes, of this part first before turning to the R side.

### 2.1. / C++ structure and changes

Table 1 lists the C and C++ files in **DEoptim** and **RcppDE**, respectively. The large file `de4_0.c` has been split into three files: one each for the core functions `DEoptim()` (which is called from R), `devol()` (which is the core differential evolution optimisation routine) and `permute()` (which is a helper function used to shuffle indices).

The evaluation function has been replaced by a base class and two virtual classes. These can now make use of objective functions written in R (as in **DEoptim**) as well as ones written in C++. Using compiled objective functions can lead to substantial speed improvements, particularly when the evaluation of the objective is ‘expensive’ relative to overall computation in the optimization algorithm. Section 3 discusses these changes in more detail.

### 2.2. R structure and changes

Table 2 lists the files and corresponding key functions. Very few changes had to be made for **RcppDE**. Keeping the interface compatible between both implementations was an important goal. As can be seen from table 2, no files or functions were added. A more detailed comparison follow below in section 4.

### 3. C / C++ changes

In this section, we will look at the changes at the C / C++ level. Figures 4 to 6 contain the...
code the highest-level C++ function: \texttt{DEoptim()} (which we renamed from \texttt{DEoptim\_C()} as there is no need for a different name at the C level relative to R). This is followed by figures 7 to 14 on the main worker function \texttt{devol()} before figure 15 compares the objective function evaluation of as the last element at the C / C++ level.

3.1. \texttt{de4\_0.c} and \texttt{deoptim.cpp}

The \texttt{DEoptim()} function (renamed from \texttt{DEoptim\_C()} as there is no need for a different name at the C level relative to R) is the entry point from R. It receives parameters, sets up the call of \texttt{devol()} and then prepares the return values.

\textbf{Part 1: Start of DEoptim()} The first part concerns itself with receiving parameters from R; figure 4 displays this. The pure mechanics of passing and receiving parameters from R are easier thanks to logic provided by the \texttt{Rcpp} package:

1. Figure 4 illustrates this point: Panel B (with code using C++) appears to be about half the size of panel A but this due in part to bringing comments on the same line as code. On the other hand, we save for example the declaration of ten \texttt{SEXP} variables as \texttt{Rcpp} objects can be converted directly to \texttt{SEXP} type.

2. Instead of using a mix of macros like \texttt{NUMERIC\_VALUE}, \texttt{INTEGER\_VALUE}, \texttt{NUMERIC\_POINTER} and so on, we have a consistent use of the \texttt{Rcpp} template function \texttt{as} with template types corresponding to base typed \texttt{int}, \texttt{double} etc. Also of note is how one matrix object (\texttt{initialpom} for seeding a first population of parameter values) is initialized directly from a parameter.

3. Parameter lookup is by a string value but done using the \texttt{Rcpp} lookup of elements in the \texttt{list} type (which corresponds to the R list passed in) rather than via a (functionally similar but ad-hoc) function \texttt{getListElement} that hence is not longer needed in \texttt{RcppDE}.

4. Here as in later code examples, care was taken to ensure that variable names and types correspond closely between both variants.

\textbf{Part 2: Middle of DEoptim()} The second part, displayed in figure 5, allocates dynamic memory for both parameters returned to R as well as for temporary objects required to store

Table 2: Source file organisation for R files in \texttt{DEoptim} and \texttt{RcppDE}
the results of intermediate computations. Again, panel A shows the C code from DEoptim whereas panel B displays the C++ code from RcppDE. One difference becomes immediately apparent: the lack of proper matrix or vector types in C. We use the classes from the Armadillo C++ library written by Sanderson (2010) and provided via the R package Armadillo by François et al. (2010).

1. Matrix objects are created in C by first allocating a vector of pointers to pointers, which is followed by a loop in which each each column is allocated as vector of appropriate length.

2. In C++, allocating a matrix is a single statement. Memory is managed by reference counting and is freed when objects go out of scope. This removes a significant portion of programmer errors.

3. Another subtle difference is in the allocations of the container holding different population snapshots, here called d_storepop: Rcpp lets us create a list object in which we store matrices, just as would in R whereas the C construct is much more complicated as we will see below.

4. A subtle point discussed more below is that RcppDE stores population members column-wise rather than row-wise. Whereas matrices on the left in panel A have dimension \( n \times k \), we allocate them as \( k \times n \) matrices in panel B.

**Part 3: End of DEoptim()** The third and last part of DEoptim() covers the actual call of the worker function devol() and the preparation of return values for R. As figure 6 shows, this section realized a significant reduction in source code size.

1. The devol() function is called: as we aim to maintain interfaces, the call is unchanged between both approaches shown in figure 6.

2. The code following the function call is very different. The new version is shorter for a number of reasons:

   (a) No need to create new temporary variables just to convert to SEXP types for return to R as the Rcpp package takes care of this: seamless conversion back to R is a key feature.

   (b) No need to allocate memory for new temporary variables (as we do not need these variables, and even if we did memory allocation would be implicit).

   (c) No need to PROTECT and later UNPROTECT such dynamic memory allocations (because this is handled automatically behind the scenes).

   (d) No need for an explicit new list object to hold the eight return variables.

   (e) No need to explicitly assign names for these eight return variables; this done implicitly while we create the returned list object.

3. Rather, a mere two statements are executed: the call to devol() followed by single call to create a return object as a list with named elements which are simply inserted—just like we would in R itself.
4. The remaining code takes care of exception handling by providing to `catch()` branches. These either forward a recognised exception to R, or (in the case of an unrecognised exception) signal a generic error.

In sum, we see how a number of (possibly small) enhancements taken together permit us to write a function which is considerably shorter and easier to read, yet fully equivalent in terms of its functionality.

3.2. de4_0.c and devol.cpp

The `devol()` function is the key part of the **DEoptim** implementation. It is also by far the largest function. We will discuss it again in different sections, each corresponding to one figure ranging from figure 7 to figure 14.

**Part 1: Start of devol()** The first part concerns the beginning of the `devol()`. The display (in figure 7) of panels A and B differs mostly in minor aspects:

1. The C version contains a declaration of a number of loop variable that are either not needed at all in the C++ version, or declared locally.
2. The urn depth is defined as a C macro and a constant variable, respectively.
3. The C++ version has an additional short block to set up the proper evaluation class for the user supplied function, depending on whether an external pointer object is passed (in which case we expect a compiled function) or not in which case an R routine is used, just like in **DEoptim**.
4. The `sortByIndex` vector is filled with index only in case strategy six has been selected as it is not used otherwise.

**Part 2: Initializations in devol()** The second part of `devol()` deals with the creation and initialization of a number of variables. The C language code in panel A is clearly more verbose and longer than the C++ code in panel B. As shown in figure 8, key differences are:

1. Initialization of matrices to zero values uses two explicit loops in the C version. In C++, we simply use the member function `zeros()` provided by the **Armadillo** library.
2. In panel B for the C++ case, the initial population in variable `initialpopm` is transposed in the C++ example. We keep each population as a column rather than a row as memory can generally be accessed faster column-wise.
3. The actual initialization of the first population is very comparable; in particular the R random number generator is called in the exact same sequence all throughout **RcppDE** so that results are in fact identical to those obtained from **DEoptim**.
4. The initial population evaluation occurs with a call to `evaluate()` in the original version, and a call of the member function of the evaluation class which will call either the supplied compiled function, or the supplied R functions.

---

1The `memset()` function could be used in the C version to avoid the loops for a minor performance gain.
Part 3: Iteration loop setup and start of population loop in `devol()`
The next part of `devol()`, shown in figure 9, starts both the main outer loop over all iterations as well as the main inner loop over all population elements. Similar to the discussion in the preceding paragraph, the new code is shorter in large part of more compact matrix expressions. Other differences are:

1. Intermediate populations are stored directly in a list, after being transposed to account for our design choice of operating column-wise. In the C code, the matrices are somewhat awkwardly ‘serialised’ into a single vector using the counter `popcnt` that incremented position by position.

2. Several other vector copies are each executed in a single statement rather than in an explicit loop.

3. At the beginning of the population loop, a vector is once more stored in a temporary variable and the permutation algorithm is called to pick suitable indices which will be used next.

Part 4 and 5: Population strategies in `devol()`
Evaluating each population member based on the user-selected strategies is detailed in both figures 10 and 11 covering the six available strategies as well as the default case. There are only fairly minor differences between both version as shown by panels A and B of both figures:

1. Instead of `if/else` branches, the new version uses a `switch` statement. This change can be beneficial as it may lead to fewer comparison, depending on the chosen strategy, and though the inner loop is executed many times, the overall benefit is still likely to be small.

2. The case-invariant initialization of `k` has been moved before the block.

3. The code for the different strategies differs very little between the initial C implementation and the newer C++ code.

Part 6: End of population loop in `devol()`
Figure 12 contains two fairly short segments that are entered once within each outer iteration after the loop over all population elements has finished. The two code segments in panels A and B of figure 12 are fairly close, with the one difference once again the element-by-element copy of vector elements (in C) versus the single statement using C++ objects.

Part 7: Special case of `bs` flag in `devol()`
Similarly, figure 13 once more shows differences chiefly due to the way interim solutions are copied.

1. Panel A has a full nine loops for copying vector or matrix elements which are not needed in panel B.

2. Panel A has a somewhat elaborate segment to use a loop to copy a first population vector to a temporary vector, copy a second into the place of the first before then copying the content of the temporary vector into the second (and likewise for the evaluation score
of these vectors). In Panel B, we simply use a single call of `swap()` member function for both the population vectors and their fitness.

We should note that this code is executed only when the user has changed the default value of false for the `bs` option in the control list for `DEoptim()`.

**Part 8: End of devol()** Finally, figure 14 contains the final portion of the `devol()` function. The population and its fitness value are saved. If the `checkWinner` option of the control structure has been changed by the user from the default value of false, a possible re-evaluation of the best population occurs and values are updated.

Next, if tracing is enabling and the iteration counter has a value which signals that tracing display should occur, then updates are printed before a few state variables are updated. The `devol()` then finishes right after restoring the state of the random number generator.

### 3.3. Evaluation functions in R and C++

Figure 15 details the code used to evaluate the user-supplied objective function. This figure is an exception: the code from `RcppDE` is much longer than the code in `DEoptim`. This is due to a key main extension in `RcppDE`: the ability to use not only an R function to describe the objective function to be minimized—but also a compiled function.

This is implemented by means of common C++ idiom: an abstract base class, here called `EvalBase`. This is an empty class which contains no code, but providing an interface containing of two public functions `eval()` and `getNbEvals()` which are virtual: the declare the interface, but provide no implementation. This is provided by two classes deriving from the abstract base class: one each for evaluating the R and the C++ function.

The class `EvalStandard` in panel B correspond most closely to the normal `evaluate()` in panel A. A function call with a set of parameters is prepared and the evaluated in an environment. Here, the function and the environment are supplied once at the beginning—and hence used to instantiate the class. Each evaluation then brings a new parameter vector.

The class `EvalCompiled` does the same, but not for the compiled function that we access via an external pointer. The support for external pointer types via type `XPtr` class in `Rcpp` was instrumental in implementing this. Similar to the standard case, the function is supplied at the beginning to instantiate the class. Later, on each evaluation call a new parameter vector is supplied.

### 4. R changes

Figures 16 and 17 display the main R function `DEoptim()` which provides the interface the user of these packages employs. A few changes have been made:

1. `DEoptim` supports variable arguments in the R function, which follows the standard set by other optimisation functions. For symmetry with the compiled function, we support just a standard vector. However, the environment in which the function and parameters are evaluated can also be supplied by the user (whereas `DEoptim` always creates a new environment). The use of the environment then permits us to pass auxiliary arguments to the function in the same way the variable arguments would.
2. RcppDE therefore has an additional argument `env` for the user-supplied environment, as well as an additional creation of a default environment if none was supplied.

3. Population matrices are passed from C++ to R as matrix objects; no copy or rearrangement has to be undertaken. This saves a block of code at the top of panel B in figure 17. Similarly, we do not have cast the population matrix as we already obtain a matrix.

None of the other functions from the files listed in table 2 were changed (apart from a trivial startup message in the .onLoad() function in file zzz.R). In other words, the control options for DEoptim() are unchanged between between both versions, as are the additional method for summarizing, printing and plotting.

5. Auxiliary files

5.1. Regression tests

A directory tests/ has been added. It contains the file compTest.R which provides a first means of both comparing results between RcppDE and DEoptim and also timing them. Three standard test functions (Wild, Rastrigin, Genrose) are run for four sets of parameter vector sizes—for both RcppDE and DEoptim. This ensures that results are identical between both implementation.

Adding full regression testing is left for a future version of RcppDE.

5.2. Demo files

Several demos have been added for RcppDE to the existing demo file already present in DEoptim. These new files are

- SmallBenchmark which runs the three standard test functions in both implementations for three small parameters sizes. As these small optimisation problems are relatively inexpensive, they are repeated a number of times and timings are obtained as trimmed means.

- LargeBenchmark which runs the three standard test functions in both implementations for three larger parameters sizes, this time without replication.

- CompiledBenchmark which runs the three standard test functions—but this time as compiled C++ functions demonstrating a significant performance gain relative to the R version.

- environment which runs a single small example showing how to pass an auxiliary parameter to the user-supplied function using an environment.

5.3. Benchmarking Scripts

The demos file from the preceding section are also being used for performance comparisons (as detailed in the next section).
Figure 1: Performance comparison for small-scale optimisation problems.

Results from our calculations using scripts included in the RcppDE package; results are included in the source package. Tests were performed using Ubuntu Linux version 10.10 in 64-bit mode on an Intel i7 ‘920’ CPU running at 2.6 GHz in hyperthreaded mode.

The files are organised as thin wrapper scripts around the demo files described in the preceding section.

6. Performance

We will divide the performance comparison in three sections, corresponding to the same small, large and compiled split detailed above in section 5.2.

Performance was measured between version 2.0-7 of DEoptim and the development versions of RcppDE preceding the 0.1.0 release of the latter.

6.1. Performance on small parameter vectors

Figure 1 displays a performance comparison on the standard objective functions Wild, Genrose and Rastrigin. Each function is evaluated at five, ten and twenty parameters, respectively. As running time for the small problems is inconsequential, we report trimmed means (excluding 10% at each side) over a set of ten replications (as shown in the script and demo files in the package and discussed above).

From figure 1, we can draw a number of conclusions:
Figure 2: Performance comparison for large-scale optimisation problems.

Results from our calculations using scripts included in the RcppDE package; results are included in the source package. Tests were performed using Ubuntu Linux version 10.10 in 64-bit mode on an Intel i7 '920' CPU running at 2.6 GHz in hyperthreaded mode.

- Performance between DEoptim and RcppDE is roughly comparable, though RcppDE has a small edge for which is consistent across functions and parameter sizes.

- Performance varies between objective functions: the Wild function with its two calls of trigonometric functions as well as five expressions of the vector $x$ is roughly twice as expensive as the Rastrigin function which has just one trigonometric function and two $x$ terms.

- The cost of increasing parameter size is larger than just linear: for all functions, $n = 20$ takes more than twice as long than $n = 10$, and likewise for $n = 5$. Note that we plotted figures 1 to 3 using a logarithmic $x$-axis which linearises the results.

6.2. Performance on large parameter vectors

Figure 2 display results from the running the same three test functions for larger parameters vectors of size fifty, one hundred and two hundred, respectively.

As in the preceding figure 1, using RcppDE rather than DEoptim on these optimization problems provides a consistent performance edge. This edge is now actually larger in both absolute and relative terms and ranges from just 3.5% (for the Wild function at $n = 50$)
6.3. Performance with compiled objective function

Using a compiled objective function can yield dramatic performance gains. Figure 3 compares results for \texttt{RcppDE} using a compiled objective function with \texttt{DEoptim} using the standard R implementations used before.

Gains can reach from (approximately) halving the observed time (for the Rastrigin function at \( n = 200 \)) to reducing it to almost one-tenth (for the Genrose function at all sizes).

6.4. Discussion

This section has demonstrated performance gains for the \texttt{RcppDE} implementation of optimisation via differential evolution relative to the \texttt{DEoptim} implementation we parted from. The gains we observed were consistent and range from small gains on small problems to moderate gains in the ten-percent range for larger problems. In both these cases, the objective functions used were written in R.

This paper also introduces a performance gain with allows the analysts to deploy differential evolution optimisation within R, but via a compiled objective function. This approach can
yield more dramatic gains as was seen in section 6.3. Of course, the ‘No Free Lunch’ theorem
still holds: writing such an objective function may well be more work, or may not always
be feasible. However, if it is possible—and the Rcpp (Eddelbuettel and François 2010) for R
and C++ integration makes it easier—then this approach could provide significant gains on
a wide range of optimisation problems.

7. Summary

Differential evolution optimization has been available for R through the DEoptim package
(Mullen et al. 2009; Ardia et al. 2010a,b). The ReppDE package presented in this paper
started from a simple question. Could we start from DEoptim and, by relying on the Rcpp
and RcppArmadillo packages, achieve what the the quip Shorter, Faster, Easier: Pick Any Three
alludes to: simultaneous improvements in code length, expressiveness (while maintaining
comprehensibility) and at the same time gain in performance?

Answering the first part is easiest. As section 3 demonstrated, and as can be seen from
figures 4 to 14 in the appendix, the C++ source code in ReppDE is now measurably shorter
that the C code in DEoptim that we built upon. While some of this change is caused by to
editing style and comment preferences, a very significant portion is due to two key sources.
First, the direct vector and matrix expressions in C++ free us from boilerplate code using
loops just to copy vectors or matrices. Second, direct R object manipulation in C++ is possible
thanks to the Rcpp package. Among other things, this makes it easier to access parameters
passed from R, and to return results back from C++ to R.

Answering the second question in the affirmative is also possible. Section 6 presented results
of consistent performance gains of Rcpp over DEoptim across all test functions and all param-
eters vector sizes that were examined in this paper. Particularly noteworthy improvements
in performance were obtained with the compiled objective functions that are possible with
ReppDE.

As for the third part and whether this makes using or extending the code easier: The proof
may very well be in the pudding. We hope to now investigate how the use of multithreaded
programming approaches, in particularly via the OpenMP framework, can further improve
the performance of optimization via differential evolution. We think that having changed the
code basis to the more compact C++ should facilitate this investigation. In the meantime,
the relative ease with which the extension for compiled objective function has been added
may be an indication of the possible benefits from using C++. So this is not yet fully proven,
but some benefits have already been demonstrated.

Concluding, we can score the approach presented here at a careful 2 1/2 out of 3 possible
points. Going from DEoptim to ReppDE has been a useful case study in applying Rcpp and
RcppArmadillo to a well-established problem. We hope that ReppDE also proves useful to
other R users.
